UCSB Scientists Discover Inner Workings of Potent Cancer Drug; Findings May Help Patients with Advanced Breast Cancer

A potent drug derived from an evergreen tree may soon save the lives of some patients with the deadliest form of breast cancer. According to the National Cancer Institute, breast cancer will claim approximately 40,000 lives in the U.S. this year.

Scientists at UC Santa Barbara, in cooperation with scientists in the pharmaceutical industry, have discovered the mechanism by which this drug kills cancer cells. The team has isolated the drug's action in the test tube as well as in cancer cells.

The results are reported in two studies published as the cover story of the October issue of Molecular Cancer Therapeutics, authored by a team of UCSB researchers. The articles feature work performed in the laboratories of Mary Ann Jordan and Leslie Wilson, professors in UCSB's Department of Cellular, Molecular and Developmental Biology.

"This anticancer drug, called maytansine, when linked to a tumor-targeting antibody, shows promising early results in clinical trials on patients with metastatic breast cancer," said Jordan. "Although the drug is not yet approved by the FDA, current clinical trials are open to new patients. And, the drug is being tested, with good
results, on other cancers, such as multiple myeloma and B-cell lymphoma."

Early clinical trials show that the drug shrank the tumors of one-third of the patients in the breast cancer study -- a strong result, according to the authors. The studies explain that the drug works by targeting the microtubules of cancer cells. Microtubules are the dynamic, rapidly growing and shortening protein filaments that help cells to divide and multiply.

"We discovered how the drug is taken up into the tumor cells," said Jordan. "We found out that it is metabolized by the cancer cells, inhibits the dynamics of cellular microtubules, and thus blocks the mitosis of the spindles in the cells, causing them to die."

Manu Lopus, a postdoctoral fellow at UCSB and first author of the first article, demonstrated that the maytansinoid molecules act directly on the microtubules and their component tubulin. Emin Oroudjev, first author of the second article, demonstrated the course of action of the maytansinoids after they enter the cancer cells. "When microtubules lose their natural ability to grow and shorten, they can no longer execute their key functions that are crucial to successful mitosis, thus preventing the cancer cells from dividing, and prohibiting cancer cell proliferation," said Lopus.

The drug was previously considered too dangerous to use, because of its toxicity to non-cancer cells. However, the team was able to show that modifying the anticancer drug by adding an antibody caused the drug to target only cancer cells, greatly reducing its toxicity.

The new drug, when linked with the breast cancer-targeting antibody, is named trastuzumab-DM1. DM1 is a synthetic derivative of maytansine, a molecule found in an evergreen tree in the genera Maytenus, which grows on several continents.

For more information on clinical trials, co-author Ravi Chari, of the pharmaceutical company Immunogen Inc., in Cambridge, Mass., suggests that interested cancer patients consult the Immunogen, Inc. Web site: https://www.immunogen.com/.

"Sometimes people say that there is no progress in the fight against cancer," said Jordan. "But there is progress on many fronts. There are many smaller advances on specific cancers. Les Wilson and I have been collaborating for 32 years, and it is very exciting and satisfying to both of us that many cancer drugs that we've worked on
that inhibit microtubule dynamics are becoming successful in the clinic and are helping people to live."

Lopus completed his Ph.D. in biotechnology at the Indian Institute of Technology in Bombay. The other first author, Emin Oroudjev, was a project scientist with the same research team at the time of the study. He received his Ph.D. from the Russian Academy of Science and now works in Santa Barbara at Bio SB.

†† Bottom photo: Fluorescence microscopy image of abnormal mitotic spindles in four breast cancer cells that were treated with antibody-linked maytansine. The chromosomes (blue) are not able to arrange in normal symmetrical functional spindles because the dynamics of the microtubules (green) are inhibited by the drug. The drug-treated cells cannot divide and ultimately die.

About UC Santa Barbara

The University of California, Santa Barbara is a leading research institution that also provides a comprehensive liberal arts learning experience. Our academic community of faculty, students, and staff is characterized by a culture of interdisciplinary collaboration that is responsive to the needs of our multicultural and global society. All of this takes place within a living and learning environment like no other, as we draw inspiration from the beauty and resources of our extraordinary location at the edge of the Pacific Ocean.
