Beach Bashing

Last winter's El Niño might have felt weak to residents of Southern California, but it was in fact one of the most powerful climate events of the past 145 years.

If such severe El Niño events become more common in the future as some studies suggest they might, the California coast — home to more than 25 million people — may become increasingly vulnerable to coastal hazards. And that's independent of projected sea level rise.

New research conducted by U.S. Geological Survey (USGS) scientists and their colleagues at UC Santa Barbara and six other institutions found that during the 2015-16 El Niño winter beach erosion on the Pacific coast was 76 percent above normal, and that most beaches in California eroded beyond historical extremes. The results appear in the journal [Nature Communications](#).

"This study illustrates the value of broad regional collaboration using long-term data for understanding coastal ecosystem responses to changing climate," said ecologist David Hubbard, an associate specialist at the Marine Science Institute. "We really need this scale of data on coastal process to understand what's going on with the ecology of the coast."

The research team assessed seasonal beach behavior for 29 beaches along more than 1,200 miles of the Pacific coast. The investigators' efforts included making 3-D surface maps and cross-shore profiles using aerial LiDAR (Light Detection and Ranging), GPS topographic surveys and direct measurements of sand quantities.

They then combined that with wave and water level data from each beach between 1997 and 2016. Winter beach erosion — the removal and loss of sand from the beach — is a normal seasonal process, but during El Niño events the extent of erosion can be more severe.

“Wave conditions and coastal response were unprecedented for many locations during the winter of 2015-16,” said lead author Patrick Barnard, a geologist with the USGS. “The winter wave energy equaled or exceeded measured historical maximums along the West Coast, corresponding to extreme beach erosion across the region.”

The 2015-16 El Niño was one of the three strongest events ever recorded, along with the El Niño winters of 1982-83 and 1997-98. From a water resources perspective though, the most recent El Niño was largely considered a dud due to the unusually low rainfall, particularly in Southern California, which received 70 percent less rain than during the past two big El Niño events.

“However, the waves that attacked our coast, generated from storms across the North Pacific, were exceptional and among the largest ever recorded,” Barnard said. “Further, the lack of rainfall means the coastal rivers produced very little sand to fill in what was lost from the beaches, so recovery has been slow.” Rivers remain the primary source of sand for California beaches, despite long-term reductions in the 20th century due to extensive dam construction.

While most beaches in the survey eroded beyond historical extremes, some fared better than others. The condition of the beach before the winter of 2015 strongly influenced the severity of erosion and the ability of the beach to recover afterward through natural replenishment processes.

Unlike California, many Pacific Northwest beaches have gained sediment in the years leading up to the 2015-16 El Niño. That’s due — at least in part — to more production of sand from local watersheds, dune growth and a series of mild winter storm seasons. Mild wave activity in the Pacific Northwest and artificial augmentation of beaches (adding sand) in Southern California prior to the winter of 2015-16 prevented some areas from eroding beyond historical landward extremes.

“It looks like climate change will bring us more El Niño events, possibly twice as many, at twice the frequency as in the past,” Hubbard said. “So this is a taste of what’s coming.

“First we need to understand the challenges, and those include the rising sea level and the fact that most of the problems occur during these peak El Niño events,” he added. “Then we need to restore or manage our coasts in ways that will enable us to deal with these events and conserve beach ecosystems. I think that’s the challenge that we as a society have to address.”

“Infrequent and extreme events can be extremely damaging to coastal marine habitats and communities,” said David Garrison, a program director in the National Science Foundation’s (NSF) Division of Ocean Sciences, which funded the research. “While this paper stresses the effect of waves and sediment transport on beach structure, organisms living on and in the sediment will also be profoundly affected.”

Beach survey collection was funded by the U.S. Army Corps of Engineers, the California Department of Parks and Recreation, the California Division of Boating and Waterways, the USGS, the Northwest Association of Networked Ocean Observing Systems and the National Science Foundation.

About UC Santa Barbara

The University of California, Santa Barbara is a leading research institution that also provides a comprehensive liberal arts learning experience. Our academic community of faculty, students, and staff is characterized by a culture of interdisciplinary collaboration that is responsive to the needs of our multicultural and global society. All of this takes place within a living and learning environment like no other, as we draw inspiration from the beauty and resources of our extraordinary location at the edge of the Pacific Ocean.
