A Changing Sea Floor

The nearshore rocky reefs of the Santa Barbara Channel are dynamic places, with populations of fish, mollusks, algae and other assorted sea life shifting in response to currents, storms and a variety of other conditions. They wax and wane, typically returning to some sort of baseline composition — a kind of standard demographic — after disturbances temporarily disrupt the neighborhood, and then subside.

But there is one event in recent history that continues to be felt: an extreme marine heatwave that rolled through the Pacific Ocean several years ago. Nicknamed “the Blob,” it consisted of abnormally warm temperatures that blanketed the waters in the Channel from 2014–2016. The Blob wreaked havoc on reef inhabitants, especially sessile invertebrates — filter feeders attached to the nearshore rocky reefs, such as anemones, tubeworms and clams.

“As sessile animals, most species are permanently attached to the substrate as adults,” said UC Santa Barbara graduate student researcher [Kristen Michaud](#), the lead author of a [paper](#) that appears in the Nature journal Communications Biology. “They cannot forage for alternate food sources and are highly dependent on the delivery of plankton.”

Six years later, the number of these creatures has bounced back, but a closer look reveals that the structure of these populations has changed — an indicator of the effects of global warming on coastal oceans.

A ‘Perfect Storm’

Marine heatwaves in the Santa Barbara Channel are not unheard of.

“They tend to be associated with El Niño events,” said [Dan Reed](#), a coastal marine ecologist and co-author of the paper. During these events, surface temperatures across the Pacific Ocean rise by a few degrees, and the typical upwelling of nutrient-rich cold water from the deep is suppressed. This affects the abundance of phytoplankton in the surface waters that rely on these nutrients, and by extension, the many sea creatures that rely on the plankton for food. In the Channel, El Niños tend to come with big winter storms that rip out kelp and scour the rocky sea floor. These events are destructive, but are a normal part of life in the Channel’s kelp forests — the sites of UCSB’s [Santa Barbara Coastal Long-Term Ecological Research \(SBC LTER\)](#) project.

“What was really different about the Blob was that in 2014 and 2015, we got all this warm water, but without the swell,” Reed said. This made it easier to suss out the effects of increased temperature on the kelp forest community without the complicating factors of storm and wave action, he explained.

“The Blob is exactly the kind of event that shows why long-term research is so valuable,” said [Bob Miller](#), principal investigator at the SBC LTER and a co-author on the paper. “If we had to react to such an event with new research, we would never know what the true effect was. Because SBC LTER is doing work designed to address how the changes in the environment affect coastal marine ecosystems, we are perfectly positioned to examine unprecedented events like this.”

According to Michaud, the anomalous heatwave was a “perfect storm” for the filter feeders. Not only did it result in a reduced abundance of food, but it also stoked the creatures’ metabolisms, leading them to require more food as temperatures rose. As a result, the average cover of sessile invertebrates across the study sites declined by 71% in 2015.

Among the filter feeders, there were winners and losers.

“The groups of animals that seemed to be the winners, at least during the warm period, were longer-lived species, like clams and sea anemones,” Michaud said, explaining that these species could have traits and feeding strategies that enable them to survive periods of stress and low food availability. The more vulnerable invertebrates were the rapid-growing and shorter-lived types such as sea squirts, sponges and bryozoans — compound organisms composed of a few to many tiny,

specialized individuals.

“But after the Blob, the story is a little different,” Michaud said. “Bryozoan cover increased quite rapidly, and there are two species of invasive bryozoans that are now much more abundant.”

According to the study, the species [*Watersipora subatra*](#), a recent invader, and the long-established [*Bugula neritina*](#) are now more prevalent in the Channel, post-Blob. There could be several reasons for the new dominance of these species, Michaud said, such as a greater tolerance for warmer temperatures compared to the natives, and more aggressive competition for space against reduced numbers of native bryozoans. The kelp forests, which were surprisingly resilient to the heat in the Santa Barbara Channel, may also have assisted in the bryozoan invaders’ quest for space by shading out competing seaweeds in the understory.

Additionally, Michaud and her colleagues found that a native sessile gastropod called *Thylacodes squamigerous*, or “scaled worm snail,” has significantly increased in abundance since the onset of the Blob. With a southern range that extends beyond Baja California, the researchers surmise that the animal may have adaptations to warm temperatures that made it robust to the Blob. Its ability to switch to alternative food sources such as kelp detritus could have given it an edge during the phytoplankton lean years.

The reshaping of the sessile invertebrate populations after the Blob are among the many shifts in the kelp forests that Michaud, Miller, Reed and colleagues at the SBC LTER have been focusing on, particularly with respect to climate change.

“Nothing’s permanent in this system,” Reed said. “Things fluctuate on the order of months, other things on the order of years.” With the decades’ worth of continuous data collected at the LTER’s study sites, scientists can watch for changes that might otherwise go unnoticed now but in the future could result in more profound effects.

The heat of the Blob may have subsided in the Channel, but the researchers expect the changes it wrought to continue, according to Miller, who has an eye on potential effects on the local food web, particularly with animals like surfperch, which forage for sessile invertebrates in the kelp forest.

“This pattern in the community structure has persisted for the entire post-Blob period,” Michaud added, “suggesting that this might be more of a long-term shift in the assemblage of benthic animals — these communities may continue to change as

we experience more marine heat waves and continued warming.”

About UC Santa Barbara

The University of California, Santa Barbara is a leading research institution that also provides a comprehensive liberal arts learning experience. Our academic community of faculty, students, and staff is characterized by a culture of interdisciplinary collaboration that is responsive to the needs of our multicultural and global society. All of this takes place within a living and learning environment like no other, as we draw inspiration from the beauty and resources of our extraordinary location at the edge of the Pacific Ocean.
