Researchers document the animal communities of a rare habitat

Santa Barbara Channel's natural oil seeps are a beach-goer's bane, flecking the shores with blobs of tar. But the leaking petroleum also creates fascinating geologic and biologic features. About 10 miles off the coast of Santa Barbara, several jet-black mounds interrupt the featureless sea floor. These asphalt volcanoes, virtually unique in the world, provide a rare habitat in a region known for its underwater biodiversity.

Marine scientists have compiled the first detailed description of the animal communities that call these formations home. The findings, published in the [Bulletin of Marine Science](#), detail the different kinds of fishes that live on and around the volcanoes.

Scientists first discovered asphalt volcanoes in the Gulf of Mexico. These vents erupt hot tar instead of lava, slowly building up smooth mounds that can be several dozen feet tall. In 2010, a team led by UC Santa Barbara Professor Dave Valentine [documented two volcanoes](#) in the Santa Barbara Channel, which they named Il Duomo and Il Duomito; the taller of the two, Il Duomo, is about 65 feet tall. The group published an account of the geology and characterized the habitat. Since then, scientists have found only one other site, off the coast of Angola.

"Even in our channel, that has lots of seeps, there's only two asphalt volcanoes that we know of," said lead author [Milton Love](#), a researcher at UC Santa Barbara's

Marine Science Institute. “So it takes an almost unique set of circumstances to form these.”

Yet, virtually nothing was known about the animals living at asphalt volcanoes aside from a brief description Valentine and his co-authors provided in their 2010 paper. So, Love and his colleagues used footage from an autonomous underwater vehicle to characterize the fish communities that inhabit these remarkable features. Their goal was to figure out who lives where and why. The team combed through eight hours of surveys — encompassing 2,743 still images — gradually building up a roster of the neighborhood.

Although fish densities were low, the team found a relatively diverse assemblage of species. Altogether, they observed 1,836 fish representing no less than 43 species. And at least 53.5% of these species were rockfishes. “This is what you would expect to find if you surveyed a tall and fairly smooth rock reef in this location,” Love said.

Certain fish preferred the volcanoes’ uniform slopes, including rockfishes like the swordspine, greenblotched and greenspotted. Meanwhile, a variety of poachers and flatfishes populated the muddy sea bottom surrounding the mounds. Oddly enough, there were haloes several meters wide around the volcanoes devoid of flatfishes. Love suspects those fish that ventured too close were spotted against the black tar and eaten.

The researchers observed a few taxa that moved between the mud and the edges of the asphalt, such as shortspine combfish, greenstriped rockfish and spotted ratfish. Notably rare were the “sheltering guild” of fishes, such as bocaccio and cowcod, which require nooks and crannies that are absent on the asphalt volcanoes’ smooth slopes, as well as the surrounding sea floor. However, “Even small amounts of asphalt in an image had a substantial effect on the species that were observed,” the authors wrote, as soft-seafloor fishes kept away from the hard tar.

Although dormant now, the asphalt volcanoes are relatively new features. “They probably developed around 40,000 years ago,” Love said. And he was quick to point out that they were quite different just a few thousand years ago. “What we see now we wouldn’t have seen even 20,000 years ago, when you had these glacial maximums and sea level minimums,” he said. At that time, the highest of these features would have been just a few dozen feet below the surface. “It would’ve had an entirely different group of fishes and invertebrates, and it would’ve had algae all

over it.”

Today, the volcanoes have a stark beauty. Colorful invertebrates pop out in sharp relief against the black substrate. “You have all kinds of sponges and deep-water corals,” Love said. A particularly striking orange animal seems to rim the edges of cracks and fissures. “Is it a sea anemone? Nobody seems to know.” The group hopes to publish an account of the invertebrate assemblages in the future.

Unfortunately, the team also found evidence of illegal fishing, including lost lines, weights and even a rockfish carcass still on the hook. Although the fish communities are typical of the area, Love believes California should protect these sites given how unique they are. “Not only are there only three places known that have this habitat, but this is the only one in shallow water,” he said.

About UC Santa Barbara

The University of California, Santa Barbara is a leading research institution that also provides a comprehensive liberal arts learning experience. Our academic community of faculty, students, and staff is characterized by a culture of interdisciplinary collaboration that is responsive to the needs of our multicultural and global society. All of this takes place within a living and learning environment like no other, as we draw inspiration from the beauty and resources of our extraordinary location at the edge of the Pacific Ocean.
